ABSTRACT

The present models are patterned after similar models published by the author (Jacchia, 1965a). The main differences consist in the lower height (90 km instead of 120 km) of the constant-boundary surface and in a higher ratio of atomic-oxygen to molecular-oxygen density $(n(O)/n(O_2) \approx 1.5$ at 120 km instead of about 1.0). Mixing is assumed to prevail to a height of 105 km, diffusion above this height. All the recognized variations that can be connected with solar, geomagnetic, temporal, and geographic parameters are represented by empirical equations.

Tables showing temperature, density, and composition as a function of height are given for exospheric temperatures ranging from 600° to 2000°K, at 100°K intervals, and for heights from 90 to 2500 km. A summary table at the end gives densities only for the same range of heights and temperatures, but at 50°K intervals in the exospheric temperature. A set of auxiliary tables is provided to help in the evaluation of the diurnal, geomagnetic, semiannual, and seasonal-latitudinal effects.

RÉSUMÉ

Les modèles présents sont des copies de modèles analogues publiés par l'auteur (Jacchia, 1965a). Les différences principales sont la hauteur plus basse (90 km au lieu de 120 km) de la surface à limites constantes et un rapport plus élevé de la densité de l'oxygène atomique par rapport à celle de l'oxygène moléculaire $(n(0)/n(0_2)=1,5$ à 120 km au lieu d'environ 1,0). On suppose qu'un mélange prévaloit jusqu'à une hauteur de 105 km, au dessus c'est la diffusion. Des équations empiriques tiennent compte de toutes les variations connues qui peuvent être reliées aux paramètres solaires, géomagnétiques, temporels et géographiques.

Nous donnons des tableaux montrant les variations de la température, de la densité et de la composition en fonction de la hauteur pour des températures exosphériques allant de 600° à 2000° K, à des intervalles de 100° K, et pour des hauteurs allant de 90 à 2500 km. A la fin, un tableau résumé donne les intensités seulement pour la même gamme de hauteurs et de températures mais à des intervalles de 50° K dans la température exosphérique. On donne aussi un ensemble de tableaux auxiliaires pour aider à évaluer les effets diurnes, les effets géomagnétiques, semiannuels, et les effets latitudinaux saisonniers.

КОНСПЕКТ

Настоящие модели сделаны по сходным моделям, которые были опубликованы автором (Якчия, 1965а). Основные различия заключаются в более низкой высоте (90 км вместо 120 км) поверхности атомного кислорода к молекулярному $(n(0)/n(0_2)\approx1,5$ вместо 1,0 на высоте 120 км). Предполагается, что смешивание преобладает до высоты в 105 км, диффузия—на большей высоте. Все замеченные изменения, которые могут быть связаны с солнечными, геомагнит—ными, временными и гесграфическими параметрами, представлены эмпирическими уравнениями.

Таблицы, представляющие температуру, плотность и состав как функцию высоты, даны для экзосферических температур в диапазоне от 600° до 2000° К через каждые 100° К и для высот от 90 км до 2500 км. Сводная таблица в конце воспроизводит высоты и температуры в тех же диапазонах, но через каждые 50° К для экзосферических температур. Представлен набор дополнительных таблиц, помогающих в оценке дневных, геомагнитных, полугодовых и сезонно-широтных эффектов.

NEW STATIC MODELS OF THE THERMOSPHERE AND EXOSPHERE WITH EMPIRICAL TEMPERATURE PROFILES

L. G. Jacchia

1. INTRODUCTION

Static diffusion models of the upper atmosphere with empirical temperature profiles were published by the author a few years ago (Jacchia, 1965a). These models have been widely used and can also be found incorporated in the U.S. Standard Atmosphere Supplements 1966 (COESA, 1966). Their main drawback is the assumed constancy of the boundary conditions at 120 km, shared by other atmospheric models (Nicolet, 1961, 1963; CIRA, 1965). Actually, both temperature and density undergo considerable variations at $120\ \mathrm{km}$, and the neglect of this fact makes the models somewhat less reliable for heights below 200 km, as was pointed out in the text that accompanied the tables. The present tables try to remedy that situation as much as possible by taking constant-boundary conditions at the height of 90 km, which closely corresponds to that of the mesopause and also of a layer of minimum variation in the global density distribution (Cole, 1961). All the available observational material, including the most recent measurements of density and composition, has been taken into account in the construction of the present tables.

This work was supported in part by Grant NGR 09-015-002 from the National Aeronautics and Space Administration.

2. COMPOSITION

We have assumed that the atmosphere is composed only of nitrogen, oxygen, argon, helium, and hydrogen, in a condition of mixing up to 105 km, and in diffusion above this height. We have adopted the sea-level composition of the <u>U.S. Standard Atmosphere 1962</u> (COESA, 1962) such as would obtain after elimination of the minor constituents and of hydrogen (which is introduced in our models at a height of 500 km). There is some evidence that for helium gravitational separation starts at a lower height than for the other constituents. To eliminate the inconvenience of a separate homopause for helium, we have had recourse to the artifice of increasing the sea-level concentration of helium by an amount such that the atmospheric densities at heights where helium appears as a major constituent be in agreement with the observed densities. This results in an erroneous helium density below 105 km — a situation we were willing to tolerate in view of the entirely negligible contribution of helium to the total density at those heights. Thus the assumed sea-level composition is as follows:

	Fraction by volume $q_0(i)$	Molecular weight $rac{m}{i}$
Nitrogen (N ₂)	0. 78110	28. 0134
Oxygen (O ₂)	0. 20955	31. 9988
Arg <u>o</u> n (Ar)	0.00934	39. 948
Helium (He)	0.00001289	4. 0026
Sum	1.00000	

The resulting sea-level mean molecular mass is $\overline{M}_0 = 28.960$.

We have assumed that any change in the mean molecular mass $\overline{\mathbf{M}}$ in the mixing region below 105 km is caused only by oxygen dissociation. Therefore, the amount of atomic oxygen present in the atmosphere is uniquely determined by \overline{M} . From 90 to 105 km we have used an empirical \overline{M} profile that had to satisfy certain conditions. Starting from a value not too different from \overline{M}_0 at 90 km, we end at 105 km with a value that would yield a concentration of atomic oxygen such that the ratio $n(O)/n(O_2)$ at 120 km would be about 1.5 and have a gradient dM/dz at 105 km roughly equal to that corresponding to the gradient in diffusion immediately above 100 km (thus minimizing the effect on the models of a change in the height of the homopause). The average observed height of the turbopause is closer to 100 than to 105 km, but we have to allow for a difference of a few kilometers between the turbopause and the effective homopause. We also constructed a model with the homopause at 100 km, which is virtually identical with the present model above 105 km, but we chose to publish the present model because it leads to a smoother \overline{M} profile across the homopause. The ratio $n(O)/n(O_2) = 1.5$ at 120 km was arrived at after many attempts to construct models with ratios from 0.5 to 4; it seems to fit best the satellite-drag data, particularly near maximum solar activity. It is larger than the ratio 1.0 used in the Jacchia 1965 models and the CIRA models, but not quite so large as advocated by Von Zahn (1967).

The adopted \overline{M} profile can be found in the tables. For computer purposes we have used a sixth-degree polynomial of the form

$$M(z) = \sum_{n=0}^{\infty} c_n (z - 100)^n \qquad (90 < z < 105; z in km) \qquad (1)$$

to represent it. The coefficients c_n are given below:

$$c_0 = 28.15204$$
 $c_1 = -0.085586$
 $c_2 = +1.2840 \times 10^{-4}$
 $c_3 = -1.0056 \times 10^{-5}$

$$c_4 = -1.0210 \times 10^{-5}$$
 $c_5 = +1.5044 \times 10^{-6}$
 $c_6 = +9.9826 \times 10^{-8}$

The number densities of the individual species i in the region from 90 to 105 km are obtained as follows. From the density ρ the total number of particles N per unit volume is computed by

$$N = A\rho/m , \qquad (2)$$

where A is Avogadro's number.

For N_2 , Ar, and He we have

$$n(i) = q_0(i) \frac{\overline{M}}{\overline{M}_0} N , \qquad (3)$$

and for O and O_2 , respectively,

$$n(O) = 2N \left(1 - \frac{\overline{M}}{\overline{M}_0}\right)$$

$$n(O_2) = N \left\{\frac{\overline{M}}{\overline{M}_0} \left[1 + q_0(O_2)\right] - 1\right\}$$
(4)

For ρ in g cm⁻³ we have used A = 6.02257 × 10²³.

PRECEDING PAGE BLANK NOT FILMED.

3. COMPUTATION OF DENSITIES AND BOUNDARY CONDITIONS

From 90 to 105 km, for a given temperature profile T(z), the density ρ was computed by integrating the barometric equation

$$d\ln \rho = d\ln \left(\frac{\overline{M}}{T}\right) - \frac{\overline{M}g}{kT} dz , \qquad (5)$$

where g is the acceleration due to gravity, and k = 8.31432 joules (°K)⁻¹ mol⁻¹, the universal gas constant.

At the height z = 90 km we have assumed the following boundary conditions:

$$\rho_1 = 3.46 \times 10^{-9} \text{ g cm}^{-3}$$
,
 $T_1 = 183^{\circ} \text{K}$.

Above 105 km the number density of each individual species n(i) was computed by integrating the diffusion equation

$$\frac{\mathrm{dn}(i)}{\mathrm{n}(i)} = -\frac{\mathrm{m}_{i}g}{\mathrm{k}T} \, \mathrm{dz} - \frac{\mathrm{d}T}{T} \, (1 + a_{i}) \quad , \tag{6}$$

where a_i is the thermal diffusion coefficient. Following Nicolet, we have used a = -0.38 for helium, and a = 0 for the other constituents.

For hydrogen we have followed Kockarts and Nicolet (1962) and fitted the equation

$$\log_{10} n(H)_{500} = 73.13 - 39.40 \log_{10} T_{\infty} + 5.5 (\log_{10} T_{\infty})^2$$
 (7)

to their concentrations at 500 km. We have assumed hydrogen to be in diffusion equilibrium above 500 km; no hydrogen densities were computed below this height. According to equation (7) hydrogen densities decrease

when the temperature increases, contrary to the behavior of all other atmospheric constituents. This should be correct in the variations with the 11-year solar cycle. According to Meier (1969), however, the variations of hydrogen in the 27-day oscillations corresponding to solar rotation are in phase with those of the other constituents. It would seem, therefore, that at heights where hydrogen is a major constituent, density variations cannot be computed in a simple fashion by just changing the exospheric temperature (see Section 12).

The acceleration due to gravity was computed from the formula

$$g = 980.665 (1 + z/R_e)^{-2} cm sec^{-2}$$
, (8)

with $R_e = 6.356766 \times 10^8$ cm. This equation (Harrison, 1951; Minzner and Ripley, 1956) is an excellent approximation to the actual value of g (centrifugal force included) for the latitude of $45^{\circ}32^{1}40^{11}$.

4. TEMPERATURE PROFILES

All temperature profiles start from a constant value $T_0 = 183^\circ K$ at the height $z_0 = 90$ km, with a gradient $G_0 = (dT/dz)_{z=z_0} = 0$, rise to an inflection point at a fixed height $z_x = 125$ km, and become asymptotic to a temperature T_∞ (often referred to as the "exospheric" temperature). Both the temperature T_x and the temperature gradient $G_x = (dT/dz)_{z=x}$ at the inflection point are functions of T_∞ ; for simplicity we have made G_x a function of T_x .

The quantity $T_{\mathbf{x}}$ is defined by the equation

$$T_x = a + bT + c \exp(\overline{k} T_\infty)$$
 , $(z_x = 125 \text{ km})$, (9)

with the constraint that $T_x = T_0$ when $T_\infty = T_0$ (i. e., for the hypothetical case in which the exospheric temperature is the same as the temperature at 90 km, namely 183°, there is no variation of temperature with height). The numerical values of the coefficients are as follows:

$$a = 444.3807$$
,
 $b = 0.02385$,
 $c = -392.8292$,
 $\overline{k} = -0.0021357$.

For $z_0 < z < z_x$ the temperature profiles are defined by a fourth-degree polynomial:

$$T = T_{x} + \sum_{n=1}^{4} c_{n} (z - z_{x})^{n} .$$
 (10)

The coefficients c_1 , c_2 , c_3 , and c_4 are determined by the following conditions:

when
$$z = z_0$$

$$\int_0^T T = T_0$$
$$G_0 = \left(\frac{dT}{dz}\right)_{z=z_0} = 0 ;$$

when
$$z = z_x$$

$$\begin{pmatrix}
G_x = \left(\frac{dT}{dz}\right)_{z=z_x} = 1.90 & \frac{T_x - T_0}{z_x - z_0} \\
\left(\left(\frac{d^2T}{dz^2}\right)_{z=z_x} = 0
\end{pmatrix}$$
(11)

These coefficients must be computed separately for every temperature profile, so their tabulation would be wasteful. The equation for G_x is justified in the following manner. The condition for having no inflections in the temperature profile in the interval $z_0 < z < z_x$ is given by

$$\frac{4}{3} < \frac{\mathbf{z}_{\mathbf{x}} - \mathbf{z}_{0}}{\mathbf{T}_{\mathbf{x}} - \mathbf{T}_{0}} \, \mathbf{G}_{\mathbf{x}} < 2 \quad . \tag{12}$$

Experiments with gradients within this range have shown that it is quite feasible to keep the quantity $(z_x - z_0)/(T_x - T_0)$ constant for all temperature profiles; the best value was found to be 1.90.

For $z > z_x$ the temperature profiles are determined by equations of the type

$$T = T_x + A \tan^{-1} \left\{ \frac{G_x}{A} (z - z_x)[1 + B(z - z_x)^n] \right\}$$
, (13)

where

$$A = \frac{2}{\pi} (T_{\infty} - T_{x})$$
; $B = 4.5 \times 10^{-6}$ for z in km; $n = 2.5$

As can be seen, continuity is provided in dT/dz when z crosses z_x . The inverse tangent was selected among several suitable asymptotic functions for its ready availability in tabulated form and in computer libraries. The presence of the corrective term $[1 + B(z - z_x)^n]$ frees the temperature profiles from strict dependence on the selected type of asymptotic function.

PRECEDING PAGE BLANK NOT FILMED.

5. VARIATIONS IN THE THERMOSPHERE AND EXOSPHERE

Several types of variation are recognized in the atmospheric regions covered by the present models. They can be classified as follows:

- 1. Variations with the solar cycle;
- 2. Variations with the daily change in activity on the solar disk;
- 3. The diurnal variation;
- 4. Variations with geomagnetic activity;
- 5. The semiannual variation;
- 6. Seasonal-latitudinal variations of the lower thermosphere;
- 7. Seasonal-latitudinal variations of helium;
- 8. Rapid density fluctuations probably connected with gravity waves.

All these variations, with the exception of the last type, are subject to some amount of regularity and can be predicted with varying degree of accuracy on the basis of ground-based observations. It is obvious that static models cannot represent all the different types of variation equally well. They should be quite adequate when the characteristic time of the variation is much longer than the time involved in the conduction, convection, and diffusion processes; when, on the other hand, it is comparable or shorter as in the diurnal variation and the geomagnetic effect - we must expect poorer results. By this we mean that, if we try to represent the observed density variations, we may have to introduce temperature variations that are not entirely correct, or vice versa. Since the largest observational material, by far, consists of density measurements, it is the density variations that we have tried to keep correct. We have no direct evidence so far that the resulting temperature variations might actually be incorrect, although it would not be surprising if they turned out to be so, to a certain degree. Temperatures derived from nitrogen profiles at various times of the day (Spencer, Taeusch, and Carignan, 1966; Taeusch, Niemann, Carignan, Smith, and Ballance, 1968) actually are in closer agreement with the J65 static models.

An effort was made in the CIRA 1965 tables to treat the diurnal variation apart; unfortunately the inadequacy of present-day theory does not justify the tremendous increase in the size of the tables if one were to cover the diurnal variation over the entire globe, instead of being restricted to one particular latitude as in CIRA 1965.

6. VARIATIONS WITH SOLAR ACTIVITY

The ultraviolet solar radiation that heats the earth's upper atmosphere actually consists of two components, one related to active regions on the solar disk and the other to the disk itself. The active-region component comes from areas of higher temperature and consists mainly of the spectral lines of highly ionized atoms, such as Fe XIV-XVI, Si IX-X, Mg X, etc.; the radiation from the clear disk comes from much less ionized atoms, such as He I-II and O IV, and the helium continuum. The active-region component varies rapidly from one day to the next in correspondence with the appearance and disappearance of active areas caused by the rotation of the sun and by spot formation; the disk component presumably varies more slowly in the course of the 11-year solar cycle. Since the radiation in the two components is different, we must expect the atmosphere to react in a different manner to each of them — and this is actually observed.

The 10.7-cm solar flux $(F_{10.7})$ is generally used as a readily available index of solar EUV radiation. It also consists of a disk component and of an active-area component, which can be separated by statistical methods by relating the observed values of the flux integrated over the whole solar disk to the corresponding sunspot numbers (Hachenberg, 1965) or, better, to sunspot areas. When the 10.7-cm flux increases, there is an increase in the temperature of the thermosphere and exosphere; for a given increase in the disk component, however, the temperature increases three times as much as for the same increase in the active-area component. Separate values of the two components of the solar flux are not readily available; fortunately we have found (Jacchia and Slowey, unpublished) that the disk component is, for all practical purposes, linearly related to the flux averaged, or smoothed, over approximately three solar rotations ($\overline{\mathbb{F}}_{10,7}$). We can, therefore, replace the relation between temperature and disk component with an equivalent relation between temperature and $\overline{F}_{10.7}$. In view of the solar-wind effect on the diurnal variation (see Section 7), it appears quite probable that the variations of both the solar EUV and the solar wind contribute to this relation.

Since the temperature varies with the hour of the day, with geographic location, and with geomagnetic activity, we must specify the parameters of these variations to which the temperature is to be referred. The temperature T_c in the equation that follows is to be the nighttime minimum of the global exospheric temperature distribution when the planetary geomagnetic index K_p is zero. We find that

$$T_c = 383^\circ + 3.32 \overline{F}_{10.7} + 1.8(F_{10.7} - \overline{F}_{10.7})$$
 (for $K_p = 0$); (14)

 $F_{10.7}$ is expressed in units of 10^{-22} watts/m²/cycles/second bandwidth.

According to Roemer (1968) the temperature variations occur with a time lag of 1.0 \pm 0.12 days with respect to those of the solar flux.

If we want to compute the average exospheric temperature corresponding to a given phase of the solar cycle, i. e., to a given value of $\overline{F}_{10.7}$, we must drop the last term of equation (14), which corresponds to the day-to-day variations of solar activity, and add half of the diurnal temperature range and the difference in temperature between average and quiet geomagnetic conditions. For this purpose, see equation (27) in Section 12.

7. THE DIURNAL VARIATION

Densities derived from satellite drag show a maximum around 2 p.m. local solar time (L.S.T.), at a latitude roughly equal to that of the subsolar point; the minimum occurs around 3 a.m. at about the same latitude with opposite sign. Thus, if we consider the atmosphere above a particular locality, the diurnal variation will undergo a seasonal change; this change, however, can be incorporated in a global description of the phenomenon by a set of suitable empirical equations (Jacchia, 1965b). The purpose of these equations is to represent the density variations by use of static atmospheric models. To this effect it appears necessary to use the temperature as an auxiliary parameter, but it must be understood that this "temperature" has no claim to accuracy, since consistency between temperature and density variation cannot be achieved, on a diurnal time scale, through static models.

We shall assume that the maximum daytime exospheric temperature T_M occurs at a latitude ϕ equal to the sun's declination $\delta_{\mathbb{O}}$, and the minimum temperature T_c at a latitude $-\delta_{\mathbb{O}}$. The ratio $T_M/T_c=1+R$ changes with the solar cycle; its variation seems to be in phase with the yearly means of the geomagnetic planetary index K_p (Jacchia, 1970a) and lags about 400 days behind those of $\overline{F}_{10.7}$, indicating that there must be a solar-wind component in the heating of the upper atmosphere.

There is also some evidence that the shape of the diurnal density curve changes with height (Jacchia, 1970b) and with solar activity; present data, however, are insufficient to establish the rules of this variation with sufficient assurance, and therefore we have assumed that the parameters that fix the shape of the curve are constant.

We shall assume that the daytime maximum temperature \boldsymbol{T}_D and the minimum nighttime temperature \boldsymbol{T}_N at a given latitude $\boldsymbol{\varphi}$ can be represented by the equations

$$T_{D} = T_{c}(1 + R \cos^{m} \eta) ,$$

$$T_{N} = T_{c}(1 + R \sin^{m} \theta) ,$$
(15)

where

$$\eta = \frac{1}{2} |\phi - \delta_{\odot}| ,$$

$$\theta = \frac{1}{2} |\phi + \delta_{\odot}| .$$

The temperature T_{ℓ} at any given point can be expressed as a function of the hour angle H of the sun (the local solar time, counted from upper culmination). Let us write

$$T_{\ell} = T_{N} (1 + A \cos^{n} \frac{\tau}{2})$$
 (16)

with

$$A = \frac{T_D - T_N}{T_N} = R \frac{\cos^m \eta - \sin^m \theta}{1 + R \sin^m \theta}$$

and

$$\tau = H + \beta + p \sin (H + \gamma) \qquad (-\pi < \tau < \pi) ,$$

where β , γ , and p are constants. It should be remembered that T_{ℓ} , which is derived from T_c , is referred to K_p = 0.

The constant β determines the lag of the temperature maximum with respect to the sun's culmination, while p introduces in the temperature curve an asymmetry, whose location is determined by γ . Replacing $T_{\widehat{D}}$ and $T_{\widehat{N}}$ from equation (15), we can write

$$T_{\ell} = T_{c}(1 + R \sin^{m} \theta) \left(1 + R \frac{\cos^{m} \eta - \sin^{m} \theta}{1 + R \sin^{m} \theta} \cos^{n} \frac{\tau}{2}\right) . \tag{17}$$

Densities derived from satellite drag are best represented by use of the following parameters:

m = 2.5
$$\beta$$
 = -37°
n = 3.0 p = +6°
 γ = +43°

The quantity R varies between 0.27 and 0.4; a good average is 0.31. If yearly running means of K_p (which we shall write as \overline{K}_p) are available, R can be computed from the relation

$$R = 0.134 + 0.090 \overline{K}_{p} . (18)$$

Otherwise, $\overline{F}_{10.7}$ can be used to compute R from the formula

$$R = -0.19 + 0.25 \log_{10} \overline{F}_{10.7}(t - 400^{d}) , \qquad (19)$$

where $\overline{F}_{10.7}(t-400^d)$ indicates the value of $\overline{F}_{10.7}$ at a rate 400 days before the date for which R is to be computed.

Table 1 gives the ratio T_{ℓ}/T_{c} , multiplied by the factor 1000, as a function of local solar time (counted from midnight) and of latitude, computed with the above parameters and with R=0.31. According to this model the hours of minimum and maximum of the daily density variation are independent of latitude and are 2.87 and 14.08 L.S.T., respectively.

A certain degree of smoothing must be expected in the curve of the daily density variation as determined from satellite drag. Neutral temperatures determined from Thomson scatter (Carru, Petit, and Waldteufel, 1967; McClure, 1969) show a rapid increase at sunrise, followed by a much slower increase to a maximum around 16^h, 2 hours later than the 14^h density maximum obtained from drag; the amplitude of the variation, a factor of 1.5, is much larger than that of our model. By smoothing, this temperature curve can be brought closer to the drag density curve, although smoothing

alone cannot possibly account for the considerable discrepancy between the two curves. In particular, there is not the slightest indication in the drag density curves of a rapid increase at sunrise (which is a prominent feature of electron temperatures). On the other hand, temperatures derived from nitrogen profiles obtained from six rocket firings from Cape Kennedy on January 24, 1967 (Taeusch et al., 1968) essentially agree in amplitude and phase with those of the present model. Also in better agreement with the model are the temperature ranges obtained from thermosphere probes (Spencer et al., 1966), from mass-spectrometer data on the Explorer 17 (Reber and Nicolet, 1965) and the Explorer 32 (Newton, 1969), and from EUV absorption (Hall, Chagnon, and Hinteregger, 1967).

Equation (17) should lead to reasonably accurate densities up to the height where hydrogen becomes an important constituent. When hydrogen can no longer be neglected, its density variations, if known, could be represented by using for hydrogen alone a fictitious "temperature" T_H different from the temperature T_H of the other constituents. A formula of the type

$$T_{H} = (1 - c)(1 + \frac{R}{2})T_{c} + cT_{\ell}$$
, (20)

could do the trick. With c = 0 the formula gives for hydrogen a constant temperature equal to the arithmetic mean between the daytime maximum and the nighttime minimum, and there is no diurnal density variation of hydrogen. With c = 1 hydrogen has the same temperature as the other constituents; i. e., the diurnal density variation of hydrogen is in phase with the one it displays during the 11-year solar cycle. With c = -1 the diurnal variation of hydrogen is reversed and is in phase with that of the other constituents. We can expect c to lie between -1 and +1; on the basis of Meier's (1969) observations there is a definite possibility that it may be negative.

8. VARIATIONS WITH GEOMAGNETIC ACTIVITY

For practical reasons we have assumed that in the temperature changes that accompany variations in geomagnetic activity the shape of the temperature profiles remains unchanged—i.e., we have related changes in an index of geomagnetic activity with changes in the exospheric temperature T_∞ and have assumed that at all heights the densities are determined by the model temperature profile ending in T_∞ . As in the case of the diurnal variation, this assumption is found to be somewhat in error because of the short characteristic time of the variations; moreover, the distribution in height of the energy dissipation involved in the phenomenon may be different from that of EUV absorption.

The density variations with geomagnetic activity can be represented with a fair degree of approximation by adding to the exospheric temperature a quantity ΔT_g , which is a function of the 3-hourly planetary geomagnetic index K_p or its equivalent a_p . We can write (Jacchia, Slowey, and Verniani, 1967)

$$\Delta T_g = 28^{\circ} K_p + 0.03 \exp(K_p)$$
 (21)

or

$$\Delta T_g = 1.00 a_p + 100^{\circ} [1 - \exp(-0.08 a_p)]$$
 (22)

The average time lag between the variations in the geomagnetic index and those in the temperature is 6.7 hours (7.2 hours at low latitudes, less than 6 hours at high latitudes). This means that to compute ΔT by equation (21) or (22) for a given time t, K or a must be taken for a time t minus 6.7 hours. There is some indication that ΔT is somewhat greater, possibly by 20% or so, at high geomagnetic latitudes. No appreciable difference in ΔT has been detected between the night hemisphere and the sunlit hemisphere. Values of ΔT from equation (21) are given as a function of K and a in Table 2.

THECEDING PAGE BLANK NOT FILMED.

9. THE SEMIANNUAL VARIATION

As is well known, geomagnetic activity is greater around the equinoxes than around solstices. This semiannual increase in geomagnetic activity results, of course, in a corresponding increase of atmospheric disturbances, which is entirely accounted for by equation (21) or (22). This apparent semiannual variation must not be confused with a true, global semiannual variation, which is evident also after the geomagnetic effect has been eliminated. This semiannual variation, with maxima in April and October and minima in January and July, has an amplitude that depends on solar activity and is roughly proportional to the smoothed 10.7-cm solar flux $\overline{F}_{10.7}$. Table 3 gives at 10-day intervals the correction ΔT_s to be applied to the exospheric temperature to account approximately for the semiannual variation. The table is computed for $\overline{F}_{10.7} = 100$, so the tabular values must be multiplied by $\overline{F}_{10.7}/100$ to obtain the actual corrections. Table 3 has been computed by using the formula given by Jacchia, Slowey, and Campbell (1969), which is reproduced below:

$$\Delta T_s = 2.41 + \overline{F}_{10.7}[0.349 + 0.206 \sin (360°\tau + 226.5)] \sin (720°\tau + 247.6),$$
(23)

where

$$\tau = \frac{d}{Y} + 0.1145 \left(\frac{1 + \sin \left[360^{\circ} (d/Y) + 342^{\circ} 3 \right]}{2} \right)^{2.16} - \frac{1}{2} \right) ;$$

d = days since January 1 ;

Y = length of tropical year in days .

The dates of u axima and minima according to this formula, with their corresponding values of ΔT_s for $\overline{F}_{10,7} = 100$, are as follows.

Secondary minimum (-16°): January 15 Secondary maximum (+28°): April 3 Primary minimum (-50°): July 30 Primary maximum (+49°): October 28

In reality the semiannual variation is not a very regular phenomenon. Both the shape and the amplitude of the variation show erratic changes from cycle to cycle; sizable residuals must be expected when using equation (23), which was obtained by fitting the observed density data from 1958 to 1965 (inclusive). King-Hele and Walker (1968) think there might be a systematic modulation of the amplitude with a cycle of about 33 months, but this effect needs confirmation.

Equation (23) seems to give a correct representation of the relative amplitudes of the density variation at different heights in the interval from 250 to 800 km. Cook (1967, 1969) found that at 1100 km the amplitude is systematically higher. Our data on the Echo 2 satellite confirm this result, but show that the excess variation that remains after subtracting equation (23) differs in shape and phase from the semiannual variation in the region 200 to 800 km. The maxima and minima show no alternation of primary and secondary, and occur some 25 days earlier, following the solstices and equinoxes by only 8 days instead of the average 33 of equation (23). We suggest that this residual semiannual variation is a result of the seasonal migration of helium: if a vertical flux accompanies the helium migration (Kasprzak, 1969), the total mass of helium in any given height layer may vary in the course of the year.

A semiannual density variation found by Cook (1969) at 90 km, which—
if confirmed—would make equation (23) inapplicable at heights below
200 km, is spurious according to Groves (1969, private communication),
and caused by an insufficient discrimination between the diurnal and seasonallatitudinal variations.

10. SEASONAL-LATITUDINAL VARIATIONS OF THE LOWER THERMOSPHERE

In the present models we have assumed that temperature and density are constant at 90 km all over the globe. In reality, seasonal-latitudinal variations are observed at that height — fairly large in temperature, although relatively small in density. All the variations we have described so far could be taken into account with a fair degree of approximation by operating on the exospheric temperature; such a procedure is obviously impossible for the seasonal-latitudinal variations, for which it is necessary to operate on the lower boundary conditions. However reluctantly, the decision to keep the lower boundary conditions constant had to be taken to prevent the models from becoming unmanageable in their complexity.

An attempt was made in the <u>U.S. Standard Atmosphere Supplements</u>, 1966 (COESA, 1966) to effect a smooth junction between the densities of lower-thermosphere models with seasonal variations and the densities of upper-atmosphere models computed by use of constant boundary conditions at 120 km. The models were limited to a fixed, intermediate latitude and to three seasons (summer, winter, and spring/fall); any greater detail would have entailed a prohibitive proliferation of tables. If we wanted to have models for every month at 15° intervals in latitude, the number of models would increase by a factor of 84!

The amplitude of the seasonal-latitudinal density variations increases very rapidly between 90 and 100 km; the maximum amplitude is apparently reached between 105 and 120 km; above this height it must decrease because above 200 km there seem to be no appreciable seasonal-latitudinal variations other than those involved in the global pattern of the diurnal variation. This means that the temperature variations, which at 100 km are in phase with the density variations, must undergo a phase inversion around 140 km and reach a maximum amplitude, in opposite phase with respect to the densities, somewhere around 150 km. While it is relatively easy to represent the density

variations in analytical, and even in tabular, form, it would be prohibitively laborious to do the same thing for the temperatures. We thought that the best that could be done was to give formulas for computing the seasonal-latitudinal variations in density, ignoring the temperature variations.

The equation we present here is an attempt to fit the seasonal variations as derived by Champion (1967) and Groves (1969, private communication). We find that the values of log ρ given by the models must be corrected by adding a quantity $\Delta \log \rho$ given by

$$\Delta \log \rho = 0.02(z - 90) \frac{\Phi}{|\Phi|} \exp \left[-0.045(z - 90)\right] \sin^2 \Phi \sin \frac{360^{\circ}}{Y} (d + 100)$$
, (24)

where φ is the geographic latitude, z the height in kilometers, Y the duration of the tropical year in days (365 or 366), and d the number of days elapsed since January 1. In Table 4 we have tabulated the maximum amplitude S of the variation as a function of height, the phase P of the variation, and $\sin^2\varphi$; $\Delta_s\log\rho$ is obtained as a product of these three quantities.

11. SEASONAL-LATITUDINAL VARIATIONS OF HELIUM

A strong increase of helium concentration above the winter pole has been revealed by mass-spectrometer measurements (Hartmann et al., 1968; Kasprzak et al., 1968; Krankowski, Kasprzak, and Nier, 1968; Müller and Hartmann, 1969), by observing the intensity of the λ 10830 resonance line of helium (Fedorova, 1967; Shefov, 1968; Tinsley, 1968) and from satellitedrag data (Jacchia and Slowey, 1968; Keating and Prior, 1968). The amplitude of the variation and its latitudinal depedence are still under investigation; the phase seems to be better established, with the maximum occurring just after the winter solstice. Under this assumption regarding the phase, we find that a flexible and relatively simple expression for the number density n(He) of helium is the following:

$$\frac{n(\text{He})}{n_0(\text{He})} = A + (B - A) \left[\left(\frac{\mathbf{\epsilon} - \delta_0'}{2\mathbf{\epsilon}} \right)^p \sin^r \left(\frac{\pi}{4} + \frac{\phi}{2} \right) + \left(\frac{\mathbf{\epsilon} + \delta_0'}{2\mathbf{\epsilon}} \right)^p \sin^r \left(\frac{\pi}{4} - \frac{\phi}{2} \right) \right], \tag{25}$$

where $n_0(He)$ is the value of n(He) given by the models, $\boldsymbol{\xi}$ the obliquity of the ecliptic, δ_{\odot} the declination of the sun at time t - Δt , and ϕ the geographic latitude.

As of now it is difficult to give reliable values for all the parameters; we can recommend the following set:

$$A=0.5$$
 , $B=2.3$; $p=2.5$; $r=4$, $\Delta t=8\;\mathrm{days}$

The value of Δt was derived indirectly, from the semiannual variation of helium at 1100 km (see Section 9), under the assumption that the phenomenene is caused by the seasonal migration of helium. Some of the numerical parameters, especially p and r, are only poorly determined and are likely to be considerably improved in the near future. In view of these uncertainties it appears to be premature to give tables of the helium variation

As can be easily seen, A and B are, respectively, the maximum and the minimum value that $n(He)/n_0(He)$ can reach. If we assume that the values we have given for them are correct, we shall have at the winter pole 2.3 times as much helium as in the tabular models, and at the summer pole 0.5 times the tabular value — a helium variation by a factor of 4.6.

12. HYDROGEN

As we mentioned in Section 3, there is some evidence that equation (7) can be used only to determine the average amount of hydrogen corresponding to a given phase of the solar cycle, but not the variations of hydrogen on a shorter time scale. To account for Meier's (1969) observations, we have followed, for our private use, a procedure that we shall briefly outline. First, we compute the average exospheric temperature \overline{T}_{∞} that corresponds to a given value of $\overline{F}_{1,0,7}$ from the formulas

$$\overline{T}_{c} = 383^{\circ} + 3^{\circ} \cdot 32 \overline{F}_{10.7} ,$$

$$\overline{T}_{\infty} = \overline{T}_{c} \left(1 + \frac{R}{2} \right) + 56^{\circ}$$
(26)

 $[\overline{T}_c$ is computed from equation (14) in which the last term has been dropped; \overline{T}_∞ is obtained by adding half of the diurnal temperature range and 56° to account for the average heating coming from the geomagnetic effect (K $_p$ = 2)]. If we choose to disregard the variations of R and use simply its average value, for which we can take 0.31, equation (26) simplifies and becomes

$$\overline{T}_{\infty} = 498^{\circ} + 3.83 \overline{F}_{10.7}$$
 (27)

We compute the hydrogen number density $\overline{n}(H)_{500}$ at 500 km from equation (7) using \overline{T}_{∞} instead of T_{∞} . For heights above 500 km we compute n(H) by integrating the hydrostatic equation for a temperature T' obtained by taking into account all the short-time-scale variations in which we believe hydrogen behaves in the manner described by Meier (1969). We do not claim that this procedure is physically justifiable, or even elegant; all we try to do is to prevent hydrogen in our models from varying in a manner contrary to observations.

PRECEDING PAGE BLANK NOT FILMED.

13. THE TABLES

Tables I to 4 are auxiliary tables designed to help in the computation of the diurnal, geomagnetic, semiannual, and seasonal-latitudinal effects when no use is made of an electronic-computer program. No auxiliary table is provided for the evaluation of the seasonal-latitudinal variation of helium, for which the parameters are still somewhat uncertain and whose effect on the total density is too complicated to be accounted for in a simple table.

Table 5 gives temperature, composition, density, and pressure scale height as a function of height for exospheric temperatures ranging from 600 to 2000°K, at 100°K intervals, and for heights from 90 to 2500 km. It should be understood that no good observational data exist above 1100 km, so that all tabular data above this height must be considered as unconfirmed extrapolation.

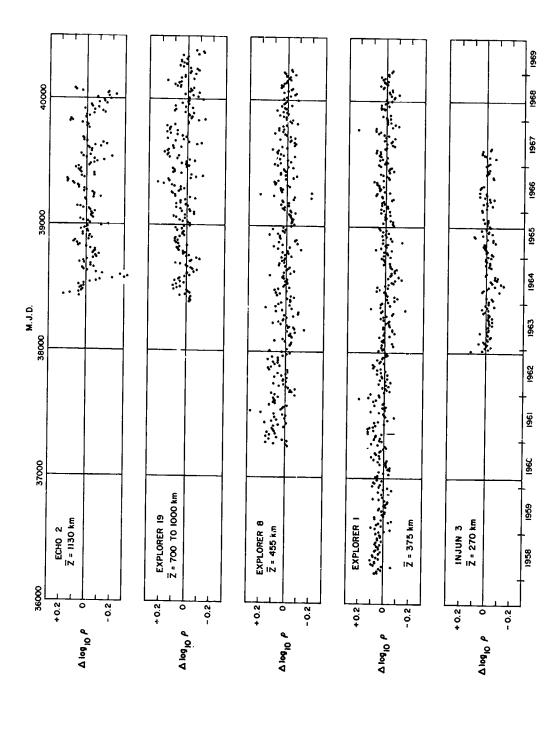

When only densities are required, Table 6 should be used to greater advantage. In it, densities only are synoptically assembled for the same heights as in Table 5, but at 50°K intervals in exospheric temperature for easier interpolation.

PRECEDING PAGE BLANK NOT FILMED.

14. COMPARISON WITH OBSERVATIONS

A comparison of the models with atmospheric densities derived from satellite-drag data obtained at the Smithsonian Astrophysical Observatory is shown in Figure 1. Ten-day means of the residuals in $\log_{10} \rho$ are plotted for five satellites with effective heights ranging from 270 to 1130 km (the "effective" height is the weighted mean of the heights above the geoid in the satellite's orbit, with the drag taken as weight; for satellites in eccentric orbits it corresponds roughly to the perigee height augmented by half the density scale height). The scatter in the residuals is due in part to errors in the drag determination and in part to the failure of the models to represent atmospheric density correctly. As can be seen, the mean systematic error is very close to zero for all satellites. Slowly varying systematic deviations, probably connected with imperfections in the relation between the exospheric temperature and the smoothed component of the 10.7-cm solar flux (equation (14)) can be detected here and there, but they never exceed 0.05 in log ρ (12% in the density). The larger, quasi-periodic oscillations in the residuals of Echo 2 and Explorer 19 are the result of our imperfect knowledge of the seasonal migrations of helium and the associated semiannual helium variation.

It should be pointed out that the densities were computed from the observed drag using a drag coefficient variable with the mean molecular mass of the atmosphere. The constants in the formula for the drag coefficient (Cook, 1966) were adjusted to give C_D = 2.2 at heights below 300 km, a value generally used by researchers. This value would correspond to an accommodation coefficient of 0.95 in the case of diffuse reflection from an oxygencoated spherical surface. Although C_D = 2.2 at 300 km is well within the margin of theoretical error, a value C_D = 2.4 is, according to Cook, the most probable. If we accept the latter value, all tabular densities should be decreased by 10%. Such a decrease would bring the densities closer to the average total densities inferred from mass-spectrometer data (which, however, show such a wide scatter that the significance of the coincidence is open to question).

Ten-day means of the logarithmic density residuals from the model for five satellites with effective heights between 270 and 1130 km. M. J. D. in abscissa is the Modified Julian Day (J. D. minus 2 400 000.5). A correction for the semiannual variation of helium has been applied to the residuals of Echo 2. Figure 1.

15. NUMERICAL EXAMPLES

Suppose we want to find the atmospheric density given by the models above a point with the following geographic coordinates:

longitude = 120°W of Greenwich, latitude = +45°,

on January 20, 1969, at $19^{h}11^{m}$ U.T. = $11^{h}0^{m}$ L.S.T., for three heights: z = 140 km, z = 350 km, z = 800 km.

We shall first compute T_c from equation (14). For that purpose we need the smoothed solar flux $\overline{F}_{10.7}$ for that date and the actual flux $F_{10.7}$ on the day before (to account for the lag of 1.0). Consulting solar records we find the following: $\overline{F}_{10.7} = 155$, $F_{10.7} = 136$, so $T_c = 863.4$. This is the minimum exospheric temperature anywhere on the globe at the desired instant, for quiet geomagnetic conditions ($K_p = 0$).

Next we shall use equation (16) or Table 1 to compute the exospheric temperature T_{ℓ} . Table 1 is computed for R = 0.31, but the actual R at the date was either 0.33 or 0.36, according to whether we use equation (18) with $\overline{K}_p = 2.17$ or equation (19) with $\overline{F}_{10.7}$ (t - 400) = 157. Let us take R = 0.345; this value is 11% greater than the value of R used for Table 1. The declination of the sun on January 20.8 was -20°0. For $\phi = +45^{\circ}$ and L. S. T. = 11 h 0 m , Table 1 gives $T_{\ell}/T_c = 1.154$. To account for the change in R,

$$T_{I}/T_{C} = 1 + 0.154 \times 1.11 = 1.171$$
.

This gives $T_{\ell} = 1011^{\circ}$.

We now must evaluate the temperature differentials ΔT_g and ΔT_s to be added to T_f to account for the geomagnetic and the semiannual effects. For ΔT_g we must first look up the value of K_p at a time 6.7 before the desired date, i. e., on January 20 at 12.5 U.T. From geomagnetic records we find for that time $K_p = 2^+(a_p = 9)$. From equations (21) or (22), or from Table 2, we obtain $\Delta T_g = +66^\circ$. Table 3 yields $\delta T_s = -15.4$ and $\Delta T_s = -15.4 \times 1.55 = -24^\circ$, so the final exospheric temperature is $T_m = 1011^\circ + 66^\circ - 24^\circ = 1053^\circ$.

At z=350 km the seasonal-latitudinal density variations, according to Table 4, are negligible; and helium is a minor constituent, so the helium variations can be neglected, too. We therefore enter Table 6 with an exospheric temperature of 1053° and find, for z=350 km, $\log_{10} \rho(g/cm^3) = -14.011$.

For z = 140 km Table 6 gives log ρ = -11.403. To this value, however, we must add a correction for seasonal-latitudinal variations in the lower thermosphere. Table 4 gives S = 0.105, P = +0.882, $\sin^2 \phi = 0.500$, from which we obtain $\Delta \log \rho = SP \sin^2 \phi = +0.046$, and the final density $\log \rho = -11.403 + 0.046 = -11.357$.

At z = 800 km helium is an important constituent, so we must take into account the seasonal-latitudinal variations of helium. To use equation (25) we must look up the declination of the sun 8 days before January 20.8; for January 12.8 we find δ_{\odot} = -21.6. With the suggested values for A, B, p, and r, we find $n(He)/n_0(He) = 1.684$. This means that the tabular number density of helium must be increased by a factor 1.684. From Table 5 we find, by interpolation, for T_{∞} = 1051°,

All other atmospheric constituents are negligible. Applying the correction factor 1.684 to $n_0({\rm He})$, we obtain $n({\rm He}) = 1.676 \times 10^6$. Taking into account the atomic masses of O and He, we find that the relative increase in total density caused by the increased helium is

$$\frac{\rho}{\rho_0} = \frac{n(O) + \frac{1}{4} n(He)}{n(O) + \frac{1}{4} n_0(He)} = 1.296 \quad ; \quad \log_{10} \frac{\rho}{\rho_0} = +0.113 \quad .$$

From Table 6, for z = 800 km, T_{∞} = 1053°, we find log ρ = -16.815. The final density, corrected for helium variation, is therefore log ρ = -16.815 + 0.113 = -16.702.

## BIOGRAPHICAL NOTE

LUIGI G. JACCHIA received his doctorate from the University of Bologna in 1932. He continued working with the university as an astronomer at its observatory.

Dr. Jacchia's affiliation with Harvard College Observatory began with his appointment as research associate in 1939. At that time he was studying variable stars. Since joining SAO as a physicist in 1956, most of Dr. Jacchia's work has been on meteors and upper atmospheric research.
